

Is the Discretionary Income Effect of Oil Price Shocks a Hoax?

Christiane Baumeister, Lutz Kilian,** and Xiaoqing Zhou****

ABSTRACT

The transmission of oil price shocks has been a question of central interest in macroeconomics since the 1970s. There has been renewed interest in this question since the large and persistent fall in the real price of oil in 2014–16. In the context of this debate, Ramey (2017) makes the striking claim that the existing literature on the transmission of oil price shocks is fundamentally confused about the question of how to quantify the effect of oil price shocks. In particular, she asserts that the discretionary income effect on private consumption, which plays a central role in contemporary accounts of the transmission of oil price shocks to the U.S. economy, makes no economic sense and has no economic foundation. Ramey suggests that the literature has too often confused the terms-of-trade effect with this discretionary income effect, and she makes the case that the effects of the oil price decline of 2014–16 on private consumption are smaller for a multitude of reasons than suggested by empirical models of the discretionary income effect. We review the main arguments in Ramey (2017) and show that none of her claims hold up to scrutiny. Our analysis highlights the theoretical basis of the discretionary income effect. We also discuss improved regression-based estimates of this effect that allow for changes in the dependence on oil and gasoline imports, and we highlight the fact that alternative estimates used by policymakers involve strong simplifying assumptions.

Key Words: Stimulus; oil price decline; discretionary income effect; expenditure share; gasoline; net oil imports.

1. INTRODUCTION

The transmission of oil price shocks has been a question of central interest in macroeconomics since the 1970s.¹ There has been renewed interest in this question since the large and persistent fall in the real price of oil in 2014–16 (see, e.g., Yellen (2015), Council of Economic Advisers (2015, 2016), Baumeister and Kilian (2017)). In the context of this debate, Ramey (2017) makes the striking claim that the existing literature on the transmission of oil price shocks is fundamentally confused about the question of how to quantify the effect of oil price shocks. In particular, she makes the case that the discretionary income effect on private consumption, which plays a central role in contemporary accounts of the transmission of oil price shocks to the U.S. economy such as Kilian

(2008, 2014), Hamilton (2009, 2013), and Blanchard and Galí (2010), “makes no economic sense” and “has no economic foundation.” Ramey suggests that the literature “has too often confused the terms-of-trade effect ... with this discretionary income effect” and makes the case that the effects of the oil price decline of 2014–16 on private consumption for a variety of reasons are smaller than estimated in Baumeister and Kilian (2017). Ramey also alleges that U.S. policymakers focus entirely on the terms-of-trade effect of changes in the real price of oil rather than the discretionary income effect.

Such strong statements raise the question of whether existing studies are really as confused as Ramey suggests or whether Ramey has perhaps misinterpreted the existing literature on the transmission of oil price shocks. Answering this question is of some importance and urgency, given the extent of recent oil price fluctuations. This article reviews the main arguments in Ramey (2017) and contrasts her reasoning with that in the existing literature. We show that none of Ramey’s claims holds up to scrutiny. Our analysis demonstrates that the discretionary income effect on private consumption is in fact closely related to the terms-of-trade effect of a change in the real price of oil on real domestic income and that U.S. policymakers are fully aware of this link. We conclude that there is no reason to rewrite the literature on the transmission of oil price shocks.

2. WHAT IS THE DISCRETIONARY INCOME EFFECT?

Ramey argues that the literature has too often confused the terms-of-trade effect, which has a sound economic basis, with the discretionary income effect, which, according to Ramey, has no economic foundation. In particular, she asserts that the estimates of the discretionary income effect reported in Edelstein and Kilian (2009), Hamilton (2009, 2013), and Baumeister and Kilian (2017), among others, are invalid. It therefore is useful to start by briefly reviewing the nature of the discretionary income effect, as discussed in academic studies and policy documents.

The idea of the discretionary income effect was first articulated in the academic literature in Edelstein and Kilian (2009). In models of the discretionary income effect, an increase in the real price of imported crude oil (and hence in the real retail price of gasoline) is akin to a tax increase from the point of view of consumers, given that the demand for gasoline is price inelastic (see Coglianese et al. 2017). As this “oil tax” is transferred abroad, the aggregate income available for other purchases declines and private consumer spending falls, causing a decline in real GDP.² In response to a fall in the real price of oil, this discretionary income effect operates in reverse, and is expected to generate a stimulus for the U.S. economy.

Underlying this analysis is the view that real oil price shocks represent terms-of-trade shocks that alter domestic spending and, through a Keynesian multiplier, affect real GDP growth. The main difference between Edelstein and Kilian’s (2009) analysis and the conventional analysis of real oil price shocks as terms-of-trade shocks is that Edelstein and Kilian explicitly recognize the fact that consumers do not purchase crude oil, but rather refined oil products such as motor fuel. This fact requires a refinement of the standard terms-of-trade shock argument. Although only a small fraction of the gasoline consumed in the United States is imported, the domestic real price of gasoline responds to shocks to the real price of imported crude oil to the extent that the gasoline sold in the United States is produced from imported crude oil. As the real price of gasoline changes in

2. Although some of the “oil tax” may ultimately be recycled, as oil-exporting countries directly or indirectly increase imports of U.S.-produced goods and services, this petrodollar recycling tends to occur with a considerable delay, if at all, and hence may be ignored in defining the shock to consumers’ discretionary income.

response to the higher cost of imported crude oil, so does the amount of real income that U.S. consumers have to give up to pay for the crude oil imports contained in the gasoline sold at gas stations.

Ramey (2017) denies the existence of this discretionary income effect on private consumption. First, she suggests that U.S. policymakers view oil price shocks as terms-of-trade shocks rather than shocks to consumers' discretionary income, implying that these explanations are mutually exclusive. Second, she asserts that the academic literature has incorrectly equated terms-of-trade shocks with relative price shocks. Specifically, she not only claims that existing studies ignored the fact that real oil price shocks are terms-of-trade shocks, but she also insists that the effect of real oil price shocks is invariant to the share of consumer spending on oil products. Third, Ramey claims that there is no theoretical support for the discretionary income effect. We address each of these claims in turn.

Ramey's first point about policymakers rejecting the notion of a discretionary income effect is clearly at odds with evidence from policy documents. For example, the Council of Economic Advisers, in its *2015 Economic Report of the President*, stresses that:

“the immediate effect of a price increase on an imported good like oil, which has a price-inelastic demand, is to decrease consumption of domestic goods and services, and, as a result, to decrease GDP” (p. 270).

The same report elaborates that:

“low oil prices benefit ... the U.S. economy [because] lower fuel costs increase real household income and stimulate consumption ... through lower gasoline prices” (p. 62).

The *2016 Economic Report of the President* is even more specific about this consumption response. It concludes that, after June 2014, “lower gasoline prices freed up income for other purchases” (p. 54).

A second example is Yellen (2011), who observes that:

“... higher oil prices lower American income overall because the United States is a major oil importer and hence much of the proceeds are transferred abroad. [...] Thus, an increase in the price of oil acts like a tax on U.S. households, and ... tends to have a dampening effect on consumer spending. [...] Staff analysis at the Federal Reserve Board indicates that a dollar increase in retail gasoline prices ... reduces household disposable income ... and exerts a significant drag on consumer spending.”

Contrary to the claim in Ramey (2017), these quotes contain every element of the discretionary income effect described by Edelstein and Kilian (2009): (1) The transmission of oil price shocks to private consumption occurs through changes in the price of gasoline; (2) the demand for gasoline is price inelastic; (3) the “oil tax” on consumer spending arises to the extent that the added spending on gasoline is transferred abroad; (4) this tax reduces discretionary income and dampens consumer spending, and, hence, real GDP.³

3. Discretionary income is sometimes referred to as disposable income. A likely reason is that the term-of-trade effect of higher oil prices may be viewed as an “oil tax” and disposable income is usually defined as after-tax income. Of course, this terminology is misleading because the “oil tax” is not considered a tax in national income accounting. More precisely, discretionary income is defined as disposable income minus real gasoline expenditures.

As noted by Baumeister and Kilian (2017), Yellen even acknowledges the fact that the effect of these gasoline price shocks depends on households' dependence on gasoline purchases, consistent with standard regression models of the discretionary income effect that allow for changes in the gasoline expenditure share of consumers. To quote Yellen (2011):

“... cheap oil encouraged households to purchase gas-guzzling cars Consequently, when oil prices quadrupled in 1973–74, that degree of energy dependence resulted in substantial adverse effects on real economic activity. Since then, however, energy efficiency in ... consumption has improved markedly” and, as a result, the effect of oil price shocks on the real economy “has decreased substantially over the past several decades.”

As to Ramey's second point, there is no evidence to support Ramey's claim that Edelstein and Kilian (2009) or related studies failed to interpret real energy price shocks as terms-of-trade shocks. In fact, Edelstein and Kilian (2009) explicitly stressed that these relative price shocks take place in an open economy:

“Implicit in this view is the assertion that higher energy prices are primarily driven by higher prices for imported energy goods, and that at least some of the discretionary income lost from higher prices of imported energy goods is transferred abroad and is not recycled in the form of higher U.S. exports.” (p. 767)

As these quotes show, Edelstein and Kilian (2009) and related studies agree with Yellen (2011) that shocks to the real price of imported commodities are terms-of-trade shocks. Edelstein and Kilian (2009) elaborate:

“In the case of a purely domestic energy price shock (such as a shock to U.S. refining capacity), it is less obvious that there is an effect on aggregate discretionary income. First, the transfer of income to the refiner may be partially returned to the same consumers in the form of higher wages or higher stock returns on domestic energy companies. Second, even if the transfer is not returned, higher energy prices simply constitute an income transfer from one consumer to another that cancels in the aggregate” (p. 767).

Thus, Ramey's assertion that Edelstein and Kilian (2009) confuse relative price shocks with terms-of-trade shocks is without basis. Ramey at some point of her discussion acknowledges this point, but suggests that the regression analysis in Edelstein and Kilian (2009) and related work remains flawed in that it proceeds, according to her, as if oil imports had nothing to do with this effect. This is not the case. In sections 3.1 and 3.2 of this paper, we examine in detail the regression models in question and make precise in what sense these models account for the role of oil imports. Not only is there no clear separation between terms-of-trade shocks and discretionary income shocks, as shown in section 3, but Ramey's claim that the effect of these shocks is invariant to the share of consumer spending on oil products is mistaken. Moreover, we show that the refinements of the standard terms-of-trade shock argument proposed by Edelstein and Kilian (2009) are necessary to account for the fact that consumers purchase gasoline, as opposed to Ramey's (2017) assumption that consumers purchase crude oil.

Ramey (2017) suggests that the best way of illustrating why the discretionary income shock is distinct from a terms-of-trade shock is in the context of a back-of-the-envelope calculation provided in Baumeister and Kilian (2017). She proposes a counterexample intended to disprove the existence of the discretionary income effect. The point of Ramey's example is to show that a change

in the relative price of a good subject to inelastic demand (say, the real price of services) has no direct effect on aggregate real consumption and real GDP. She concludes that a change in the relative price of oil therefore has no direct effect on real consumption and real GDP either. Closer examination, however, reveals that her example is not a counterexample to Edelstein and Kilian's (2009) analysis of the effect of changes in the real price of imported crude oil. Although the discretionary income of an individual consumer, all else equal, is reduced by the higher real price of services, if none of the services in question are imported, the income generated by purchases of services is recycled within the domestic economy, leaving aggregate consumer spending unaffected, as long as all consumers have the same propensity to consume.⁴ Thus, the effect of a change in the real price of services on aggregate discretionary income and on aggregate spending is zero by construction, and there is no contradiction at all. Rather than undermining the argument in Baumeister and Kilian (2017), Ramey's example underscores the importance of carefully verifying all conditions for the existence of a discretionary income effect, as stated in Edelstein and Kilian (2009).

Finally, as to Ramey's claim that the discretionary income effect discussed in Edelstein and Kilian (2009) lacks any economic foundation, sections 3.4 and 3.5 show that this view is mistaken. The economic relationships underlying the regression models of the discretionary income effect can, in fact, be derived from a fully specified New Keynesian DSGE model, as described in Blanchard and Galí (2010). Our analysis shows that the discretionary income channel of the transmission of oil price shocks is equivalent to what Ramey refers to as a shift in domestic real income arising from shocks to the price of imported crude oil. This shift in real domestic income is also commonly referred to as an "oil tax," when discussing unexpected oil price increases (see, e.g., Bernanke (2006); Edelstein and Kilian (2009); Yellen (2011); Baumeister and Kilian (2017)). Bernanke (2006) and Edelstein and Kilian (2009), equivalently, refer to shifts in consumers' purchasing power associated with changes in the real price of imported crude oil. All these terms refer to essentially the same phenomenon.⁵

3. ARE THE REGRESSIONS USED IN ESTIMATING THE DISCRETIONARY INCOME EFFECT MISSPECIFIED?

Baumeister and Kilian (2017) quantify the discretionary income effect based on estimates of a linear regression model of the relationship between changes in real U.S. private consumption and changes in consumers' purchasing power associated with gasoline price fluctuations, controlling for the evolution of the share of motor fuel expenditures in total consumer expenditures. Their

4. As discussed in Hamilton (2013, 2017), among others, to the extent that the marginal propensity to spend is not the same, an increase in the relative price may affect aggregate spending even in a closed economy. Given that the price elasticity of gasoline demand is comparatively low, an exogenous increase in the real price of gasoline causes a reduction in consumers' discretionary income. Although in a closed economy consumers' increased spending on gasoline represents income for someone else, by construction, it may take considerable time for this income to be returned to consumers in the form of company profits, royalties, or dividends paid to shareholders, or to be spent by oil companies in the form of increased investment expenditures. In a Keynesian model, differences in the marginal propensity to spend thus may affect the overall level of spending and hence the business cycle. Given our focus on the terms-of-trade effect, our discussion abstracts from this additional channel of transmission.

5. Ramey herself at times refers to an "income effect." We do not find this terminology precise or useful, because the effect in question is distinct from the income and substitution effects associated with a relative price change in a closed economy. It arises only in response to an unexpected change in the price of an imported good whose demand is price inelastic. Likewise, this effect is sometimes called a wealth effect in applied work. We do not use this terminology because a wealth effect more properly refers to changes in the valuation of assets in response to oil price shocks (see, e.g., Kilian, Rebucci and Spatafora 2009).

approach is in turn a refinement of the original regression analysis in Edelstein and Kilian (2009). Ramey (2017) argues that this regression specification is, according to her, inconsistent with the interpretation of oil price shocks as terms-of-trade shocks, as discussed in Backus and Crucini (2000) and Kehoe and Ruhl (2008), for example, and is fundamentally misspecified.

In making her case that the Baumeister-Kilian regression framework is misspecified, Ramey focuses on a simplified version of the standard national income accounting identity

$$Y = C + I + G + X - M,$$

where Y is real GDP, C is private consumption, I is investment, G is government spending, and $X - M$ is the external balance. Ramey postulates an economy in which $I = G = 0$ and $X - M = 0$ such that

$$Y = C.$$

She then allows for two goods, oil and a non-oil good, such that in nominal terms

$$P_{oil}Y_{oil} + P_{noil}Y_{noil} = P_{oil}C_{oil} + P_{noil}C_{noil},$$

where P 's denote prices, Y 's denote quantities produced domestically and C 's quantities consumed. Rearranging this identity yields

$$C_{noil} = Y_{noil} + \frac{P_{oil}}{P_{noil}}(Y_{oil} - C_{oil}). \quad (1)$$

Equation (1) highlights that if a country is a net oil importer, so $Y_{oil} - C_{oil} < 0$, an increase in the real price of oil will lower domestic income, whereas it will raise real income if $Y_{oil} - C_{oil} > 0$. There is, of course, universal agreement on this accounting identity and its interpretation. What is not clear is why Ramey (2017) concludes from this equation that the regression models used in Edelstein and Kilian (2009), Hamilton (2009), and Baumeister and Kilian (2017), among others, are fundamentally misspecified and make no economic sense. The remainder of this section seeks to clarify the merits of this claim.

Equation (1) suggests a tight relationship between non-oil consumption and net oil imports. It should be noted, however, that, in a more realistic model, that relationship is not clear-cut at all. If we allow for nonresidential investment expenditures in this accounting identity, for example, it becomes indeterminate by how much non-oil consumer expenditures and by how much business investment expenditures must fall to accommodate the loss in real income experienced by a net oil-importing economy. This means that the argument outlined by Ramey is incomplete. We need to specify a mechanism to explain by how much non-oil consumer expenditures in this economy are affected by this terms-of-trade shock. Edelstein and Kilian (2009) propose such a mechanism, consisting of four elements:

1. As the real price of crude oil increases, so does the real price of gasoline. The extent of this price increase depends on the cost share of crude oil in producing gasoline.
2. Because the demand for gasoline is price inelastic, consumers spend more on gasoline than before the gasoline price increase.
3. To the extent that the revenue from gasoline sales is transferred abroad and not returned to the U.S. economy, consumers' aggregate discretionary income (defined as after-tax real income minus real gasoline expenditures) falls, resulting in lower domestic aggregate demand.

4. In a Keynesian model, this reduction in aggregate demand may cause a decline in real GDP.

It is important to stress that the extent to which discretionary income falls depends on the extent to which the economy relies on net imports of crude oil. If the economy were self-sufficient in crude oil, for example, there would be no change in consumers' aggregate discretionary income. Ramey (2017) suggests that the mechanism described by Edelstein and Kilian (2009) implies that any fall in relative prices would cause a consumption stimulus, as long as demand is inelastic. Her interpretation, however, is missing Edelstein and Kilian's point that a discretionary income effect arises only to the extent that the real gasoline expenditures are transferred abroad and are not returned to the U.S. economy in the form of higher U.S. exports.

Next, we elaborate on a number of special cases of equation (1). It is useful to start the discussion with the case of a country that does not produce any crude oil domestically. All oil is imported. The situation of a country that produces crude oil domestically in addition to importing crude oil is discussed in sections 3.2 and 3.3.

3.1. Case 1: The Baseline Model without Domestic Oil Production

In the absence of domestic oil production, equation (1) simplifies to

$$C_{noil} = Y_{noil} - \frac{P_{oil}}{P_{noil}} C_{oil}, \quad (1')$$

where P_{oil}/P_{noil} may also be viewed as the terms of trade because oil is the import good and the non-oil good is the export good. In other words, an increase in the price of oil expressed in units of the non-oil consumption good, all else equal, reduces the amount of the non-oil consumption good available for domestic consumption, because more of this good must be used to pay for the crude oil imports. Equivalently, we may write equation (1') as $Y_{noil} - C_{noil} = P_{oil} C_{oil} / P_{noil}$, highlighting the fact that crude oil imports must be financed by a trade surplus in the non-oil consumption good. This case is typical for many oil-importing countries. It also provides a useful starting point for our discussion.

Although equation (1') helps us understand the central tradeoff between domestic consumption and crude oil imports, it is overly simplistic, even if we follow Ramey in abstracting from investment expenditures. Most importantly, this accounting identity is misspecified in that crude oil is not part of personal consumption expenditures. Consumers purchase refined products such as heating oil, diesel, and gasoline rather than crude oil. This distinction matters. Given the cost share of crude oil in producing gasoline of about half, a 50% decline in the real price of crude oil translates to a 25% decline in the retail price of gasoline only. Hence, it does not make economic sense to relate consumer purchase decisions to changes in the real price of crude oil, as proposed by Ramey (2017). Instead, we need to focus on consumer expenditures on refined products and the corresponding product prices. Of these products, heating oil may be safely ignored because most U.S. households rely on other forms of home heating, including natural gas and electricity (see Davis and Kilian 2011). Hence, Baumeister and Kilian (2017), for example, focus on consumer expenditures on motor fuel, to which we will refer, somewhat imprecisely, as gasoline in this paper.

A key point of contention is Ramey's (2017) suggestion that—in the context of case 1—we should treat the increase in the real value of the imported oil (or its gasoline equivalent), caused by an unexpected increase in the real price of oil, as the terms-of-trade shock in regression analysis. She proposes relating the growth rate of overall consumption to this measure of the terms-of-trade

shock. This argument is not persuasive. Clearly, the negative stimulus associated with this unexpected decline in consumer purchasing power will be larger in an economy in which most domestic output is used to pay for energy imports than in an economy that is not very dependent on energy imports. Put differently, if a given increase in real domestic income is enough to raise the consumption growth rate by 2%, when gasoline consumption amounts to 50% of total consumption, one would not expect the same stimulus, when gasoline consumption amounts only to 1% of total consumption. Thus, it is essential that we normalize the real gasoline price shock, before fitting regression models. A formal derivation of this point is discussed in section 3.5.

Based on the work of Edelstein and Kilian (2009), we can address this concern by measuring the increase in consumer purchasing power arising from lower gasoline prices by

$$-\frac{C_t^{gas} P_{t+1}^{gas} / P_{t+1}^{PCE} - C_t^{gas} P_t^{gas} / P_t^{PCE}}{C_t^{ngas} P_t^{ngas} / P_t^{PCE}}, \quad (2)$$

where $C_t^{gas} P_t^{gas} / P_t^{PCE}$ denotes the real cost of purchasing C_t^{gas} in period t at the old gasoline price P_t^{gas} , $C_t^{gas} P_{t+1}^{gas} / P_{t+1}^{PCE}$ denotes the real cost of purchasing C_t^{gas} in the following period at the new gasoline price P_{t+1}^{gas} , and $C_t^{ngas} P_t^{ngas} / P_t^{PCE}$ denotes the real cost of purchasing the non-gasoline consumption good, all expressed in units of the domestic consumer basket, valued at P_t^{PCE} .⁶ The central idea of Edelstein and Kilian (2009) is that we need to focus on the change in the real price of gasoline triggered by the shock to the real price of imported crude oil in quantifying the effects of this terms-of-trade shock on private consumption. Equation (2) expresses the change in real expenditures on oil imports (expressed as their gasoline equivalent) as a fraction of real expenditures on the non-gasoline consumer good. Multiplying this expression by P_t^{gas} / P_t^{ngas} and rearranging yields

$$-\left(\frac{C_t^{gas} P_t^{gas}}{C_t^{ngas} P_t^{ngas}} \right) \cdot \left(\frac{P_{t+1}^{gas} / P_{t+1}^{PCE} - P_t^{gas} / P_t^{PCE}}{P_t^{gas} / P_t^{PCE}} \right),$$

which can be approximated by

$$-\left(\frac{C_t^{gas} P_t^{gas}}{C_t P_t^{PCE}} \right) \cdot \left(\frac{P_{t+1}^{gas} / P_{t+1}^{PCE} - P_t^{gas} / P_t^{PCE}}{P_t^{gas} / P_t^{PCE}} \right),$$

given that the share of gasoline in total consumer expenditures is small. In other words, the change in consumer purchasing power (or discretionary income), denoted by PP_t , that is associated with the terms-of-trade shock approximately equals the percent change in the real price of gasoline weighted by the nominal share of gasoline expenditures in total consumer expenditures.⁷ By construction, $PP_t < 0$, if the real price of gasoline rises unexpectedly, and $PP_t > 0$, if the real price of gasoline falls unexpectedly.

Under the additional empirically supported assumption that consumers employ a no-change forecast of the real price of gasoline, PP_t may be viewed as a shock to discretionary income or, equivalently, to consumers' purchasing power (see, e.g., Anderson et al. (2013); Baumeister and Kilian (2016, 2017)). Given the evidence in Kilian and Vega (2011), we impose the identifying assumption that PP_t is predetermined with respect to the U.S. economy. As shown in Baumeister and

6. Note that Edelstein and Kilian (2009) deflate all nominal prices by the overall consumer price index rather than the price index of the non-gasoline consumption good. Given the small expenditure share of gasoline, this difference is immaterial in practice.

7. In applied work, it is common to approximate the gasoline expenditure share not by the share at the end of the month preceding the real gasoline price change, but rather by the average gasoline expenditure share in the current month.

Kilian (2017), this allows one to consistently estimate the cumulative effects of purchasing power shocks from the stationary regression model

$$\Delta c_t = \sum_{i=1}^6 \beta_i \Delta c_{t-i} + \sum_{i=0}^6 \gamma_i PP_{t-i} + u_t, \quad (3)$$

where u_t denotes the regression error and Δc_t the percentage growth rate of U.S. real private consumption. Thus, far from ignoring the role of oil imports and gasoline imports, this specification is consistent with a world in which all oil is imported. This is not the only interpretation of this regression model, however, as shown next.

3.2. Case 2: A Model with a Constant Share of Domestic Oil Production in Oil Consumption

Having discussed the special case of an economy without domestic oil production, we now turn to the more general case in which some crude oil is produced domestically and some is imported. Recall that in this case

$$C_{noil} = Y_{noil} + \frac{P_{oil}}{P_{noil}}(Y_{oil} - C_{oil}). \quad (1)$$

Equivalently, we may write that $Y_{noil} - C_{noil} = -P_{oil}(Y_{oil} - C_{oil})/P_{noil}$ such that net oil imports must be financed by a trade surplus in the non-oil good. In the case of the United States, $C_{oil} > Y_{oil}$ and the oil trade balance is negative. It is useful to first consider the case of a constant oil import share. For expository purposes, suppose that every period, half of the crude oil consumed by the economy is produced domestically and the other half is imported. In that case $Y_{oil} = 0.5C_{oil}$, and we can write

$$C_{noil} = Y_{noil} - \frac{P_{oil}}{P_{noil}} 0.5C_{oil}. \quad (1'')$$

It may seem that regression model (3) would be invalidated by this change in assumptions, but this is not the case. The key difference, after expressing this model equivalently in terms of gasoline prices and quantities, is that the change in purchasing power now depends only on 50% of real gasoline consumption:

$$-\frac{0.5C_t^{gas} P_{t+1}^{gas} / P_{t+1}^{PCE} - 0.5C_t^{gas} P_t^{gas} / P_t^{PCE}}{C_t^{ngas} P_t^{ngas} / P_t^{PCE}}. \quad (2'')$$

As a result, the change in purchasing power now is only half as large as before:

$$-0.5 \left(\frac{C_t^{gas} P_t^{gas}}{C_t^{ngas} P_t^{PCE}} \right) \cdot \left(\frac{P_{t+1}^{gas} / P_{t+1}^{PCE} - P_t^{gas} / P_t^{PCE}}{P_t^{ngas} / P_t^{PCE}} \right).$$

This change in the definition of PP_t does not affect the estimate of the cumulative effect of the purchasing power shocks based on model (3), however, because the factor of 0.5 is automatically absorbed into the estimate of the slope coefficient, when fitting the original model specification (3) without adjusting the PP_t measure. Put differently, as long as the share of the oil consumed by the U.S. economy is constant, the estimates of the cumulative effect of the terms-of-trade shock on private consumption remain valid. We do not even need to know what that share is. Thus, the implicit assumption in the work of Edelstein and Kilian (2009) and others was not that there is no domestic oil production, but that the share of domestic oil production is approximately constant. The model

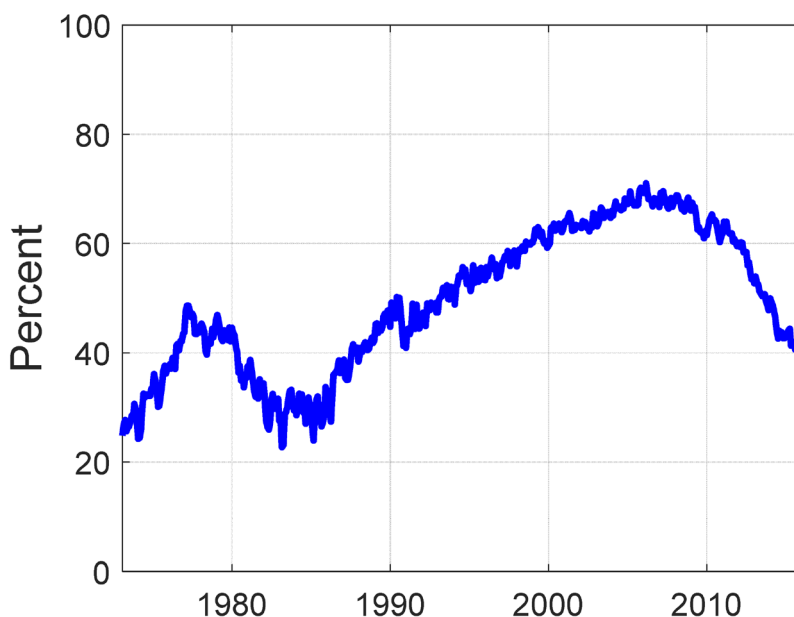

is much more general than it may have seemed at first sight and allows for a share of oil imports in oil consumption of less than 1.

3.3. Case 3: A Model with a Variable Share of Domestic Oil Production in Oil Consumption

Of course, the dependence of the U.S. economy on imports of crude oil and gasoline has not remained constant over time, especially not in recent years during the shale oil revolution (see Kilian 2017). Figure 1 plots the fraction of U.S. consumer expenditures on gasoline that is transferred abroad. The rationale for this measure is as follows. If all gasoline consumed in the United States were imported, there would be no need for an adjustment of consumer expenditures and the weight would be 1. If some gasoline is imported, the proceeds from gasoline sales going directly abroad can be captured by weighting the gasoline expenditure share by the share of gasoline that is imported. We also need to incorporate the share of gasoline that is not imported, however, to the extent that this gasoline is produced from imported crude oil. That component is captured by weighting the fraction of gasoline produced domestically by the fraction of net crude oil imports in the total use of crude oil by the U.S. economy. Figure 1 shows the sum of these two components, expressed as a percentage of consumer expenditures on gasoline.

Figure 1 shows that this import dependence measure generally increases, as the price of oil rises, and decreases, as the price of oil falls. The average share is 49%, but at times the share dropped to 25% or reached 70%. To the extent that this share at a given point in time is above or below the average share of 49%, one would expect the regression model (3) to overpredict or underpredict the cumulative effects of terms-of-trade shocks associated with oil price fluctuations.

Figure 1: Adjustment Factor for the U.S. Dependence on Gasoline and Crude Oil Imports, 1973.1–2016.3

Notes: Authors' calculations based on data in the U.S. Energy Information Administration's *Monthly Energy Review*, as discussed in the text. This adjustment factor measures the extent to which U.S. consumer gasoline expenditures are transferred abroad. It accounts for time variation in the share of gasoline imports in U.S. gasoline consumption, as well as time variation in the share of U.S. net crude oil imports in the domestic use of crude oil. The underlying data have been seasonally adjusted.

This point has indeed been ignored in the existing literature or has been thought to be of secondary importance. As a result of the fluctuations in this share, one would expect regression model (3) to be reasonably accurate only during periods when the share of domestic oil production in the use of oil is close to its long-run average. That was indeed the argument made by Baumeister and Kilian (2017) in defense of their original approach to modelling the 2014Q3–2016Q1 episode. That study observed that in mid-2014 the share of domestic oil production was close to its long-run average of 49%, suggesting that the estimates of model (3) should be useful in analyzing this episode. In contrast, for the episode of the 1986 oil price decline, this assumption is invalid because at that point in time the share was only 34% (see Figure 1).

One way of handling this concern would be the use of time-varying coefficient regression models, but such models are prone to overfitting and their estimates can be sensitive to the choice of Bayesian priors. As shown by Baumeister and Kilian (2017), an alternative and more direct way of quantifying the importance of changes in the dependence of the U.S. economy on oil and gasoline imports is to directly incorporate this evolution in the construction of the purchasing power shock. A simple approximation is to weight U.S. consumer expenditures on gasoline by the share of the proceeds going abroad, resulting in an alternative definition of purchasing power shocks,

$$-\frac{C_t^{gas} P_t^{gas}}{C_t P_t^{PCE}} \cdot \left(\frac{P_{t+1}^{gas} / P_{t+1}^{PCE} - P_t^{gas} / P_t^{PCE}}{P_t^{gas} / P_t^{PCE}} \right) \cdot \left(s_t^{gasoline\ imports} + (1 - s_t^{gasoline\ imports}) s_t^{net\ oil\ imports} \right),$$

where $s_t^{gasoline\ imports}$ is the seasonally adjusted share of U.S. motor gasoline imports in total U.S. motor gasoline consumption, as reported by the U.S. Energy Information Administration, and where $s_t^{net\ oil\ imports}$ is the seasonally adjusted share of U.S. net crude oil imports in the total use of crude oil by the U.S. economy, as defined in Kilian (2017). The adjustment factor by which we multiply the original PP_t measure corresponds to the share shown in Figure 1. This alternative measure of shocks to consumer's purchasing power (or discretionary income), denoted by $PP_t^{alternative}$, is not only more relevant for understanding the dependence of U.S. consumers on imports of crude oil and gasoline than the share of net imports in petroleum products supplied, as reported by Ramey (2017), but it also avoids the ad hoc aggregation of crude oil and refined products. It should be kept in mind, however, that even $PP_t^{alternative}$ is only an approximation, because it ignores changes in oil and gasoline inventories, because it assumes that the net share of imported crude oil is the same in the production of all refined products, because it does not differentiate between gasoline and other motor fuel, and because it makes no allowance for changes over time in the extent of petrodollar recycling from abroad.

One advantage of this alternative specification is that we can directly evaluate the empirical content of Ramey's concern regarding changes in the dependence of the U.S. economy on crude oil imports by comparing the estimates of the discretionary income effect based on baseline specification (3) with the estimates based on the alternative specification

$$\Delta c_t = \sum_{i=1}^6 \beta_i \Delta c_{t-i} + \sum_{i=0}^6 \gamma_i PP_{t-i}^{alternative} + u_t, \quad (3')$$

which controls for variation in the dependence of the U.S. economy on imports of crude oil and gasoline. We can also verify the conjecture in Baumeister and Kilian (2017) that we may still rely on the baseline model, as long as the import share is near its long-run average in the episode of interest.

Figure 2 compares the original and the alternative measure of purchasing power shocks. The purchasing power shock used in the baseline model (shown in the upper panel) without loss of generality has been scaled by the average adjustment factor of 0.49, so the magnitude of the pur-

chasing power shocks can be compared directly with that of the shocks in the lower panel, which have been adjusted by the factor shown in Figure 1. The largest differences arise during 2005–09. At many other times, the differences are negligible. For example, Figure 2 shows that the purchasing power shock under the alternative specification is much smaller during 1986Q1–1987Q3. In contrast, during 2014Q3–2016Q1, the purchasing power shocks are remarkably similar under both specifications. Thus, to the extent that the estimate of the discretionary income effect during 2014Q3–2016Q1 is affected by the definition of the purchasing power shock, that difference must arise through differences in the slope parameter estimates of the regression model rather than the measurement of the purchasing power shocks.

The first column of Table 1 shows that, according to the baseline model (3), the decline in the price of oil after June 2014 raised U.S. real private consumption by 1.2 percentage points cumulatively by the end of 2016Q1. The implied stimulus for U.S. real GDP is 0.7 after accounting for the 69% share of private consumption in GDP and allowing for an import propensity of 15%. Controlling for the dependence on oil and gasoline imports, as shown in the second column of the table, implies a somewhat smaller stimulus of 0.9 percentage points for consumption (or 0.5 percentage points for real GDP).⁸ Nevertheless, the estimates are in the same ballpark. In both cases, there is

8. The estimates in Table 1 for the alternative model do not match those in Baumeister and Kilian (2017) exactly due to a data transcription error in that paper, which has been corrected in the current analysis. For example, the cumulative effect on consumption in model (3') is 0.87 rather than 0.92, as reported in Baumeister and Kilian (2017).

clear evidence of a modest stimulus associated with the discretionary income effect. As expected, controlling for the dependence on oil and gasoline imports changes the estimates without overturning the substantive conclusions based on model (3).

From a policy point of view, the difference between a stimulus of 0.7 percentage points for U.S. real GDP and a stimulus of 0.5 percentage points is negligible. Thus, Ramey's conjecture that the baseline results in Baumeister and Kilian (2017) are an artifact of their failure to model time variation in the dependence of the U.S. economy on imports of gasoline and crude oil is clearly rejected. We conclude that, on a priori grounds, the alternative specification (3') proposed by Baumeister and Kilian (2017) may be more appealing, but that the two specifications generate similar results for the 2014–16 episode, contradicting Ramey's claim. Moreover, which specification is used does not affect the substantive conclusion in Baumeister and Kilian (2017) that the net stimulus for the U.S. economy implied by lower oil prices after June 2014 has been close to zero.

In the last two columns of Table 1 we repeat this exercise for the 1986–87 episode, which was characterized by a similar, if much smaller sustained decline in the real price of oil. For this episode, one would expect the baseline model to be less accurate, given that the economy was less dependent on oil and gasoline imports in 1985Q4 than in 2014Q2, as reflected in the alternative purchasing power measure in Figure 2. The baseline model (3) implies that, in the seven quarters following 1985Q4, U.S. real private consumption cumulatively increased by 0.8 percentage points, as a result of the decline in the real price of oil that started in early 1986, implying a stimulus of 0.5 percentage points for real GDP. In contrast, the alternative model (3') suggests a cumulative increase in private consumption of only 0.4 percentage points and an implied stimulus for U.S. real GDP of only 0.2 percentage points (see Table 1). Although this difference is not much larger in absolute terms than in the 2014–16 episode, it is at least twice as large in relative terms. This example illustrates that the adjustment factor may matter, providing empirical support for Baumeister and Kilian's decision to model the 1986–87 episode based on model (3') rather than (3).

3.4. Yet Another Definition of the Purchasing Power Shock?

Given Ramey's insistence that the approach described in sections 3.2 and 3.3 is at odds with the policy consensus, it is useful to relate our approach to the definition of purchasing power shocks used in Council of Economic Advisers (2014, p. 25):

$$\left[as_t + (1-a)\bar{s}\right] \cdot \left(\frac{P_{t+1}^{oil} - P_t^{oil}}{P_t^{oil}}\right),$$

where $s_t = (M_t^{oil} - X_t^{oil})P_t^{oil} / (Y_t P_t^Y)$, \bar{s} is the sample average of s_t , $(M_t^{oil} - X_t^{oil})P_t^{oil}$ denotes nominal net oil imports, Y_t is real GDP, and P_t^Y is the GDP deflator.⁹ The parameter a is either 0 or 1. For $a = 0$, the Council of Economic Advisers measure of the purchasing power shock reduces to

$$\bar{s} \cdot \left(\frac{P_{t+1}^{oil} - P_t^{oil}}{P_t^{oil}} \right),$$

and for $a = 1$, it reduces to

$$s_t \cdot \left(\frac{P_{t+1}^{oil} - P_t^{oil}}{P_t^{oil}} \right).$$

It can be shown that these definitions under suitable simplifying assumptions may be derived from the original and the alternative definition of the purchasing power shock, respectively, as discussed in sections 3.2 and 3.3. For expository purposes, we consider the case of $a = 1$. Recall our alternative definition of the purchasing power shock as

$$-\frac{C_t^{gas} P_t^{gas}}{C_t P_t^{PCE}} \cdot \left(\frac{P_{t+1}^{gas} / P_{t+1}^{PCE} - P_t^{gas} / P_t^{PCE}}{P_t^{gas} / P_t^{PCE}} \right) \cdot (s_t^{gasoline imports} + (1 - s_t^{gasoline imports}) s_t^{net oil imports}),$$

where $s_t^{net oil imports} \equiv (M_t^{oil} - X_t^{oil})P_t^{oil} / (Y_t^{oil} + M_t^{oil} - X_t^{oil})P_t^{oil}$, and suppose that $C_t = Y_t$, which amounts to imposing that $I = G = X - M = 0$, as in Ramey's analysis. Further suppose that gasoline and oil are the same good such that $s_t^{gasoline imports} = 0$, $P_t^{gas} = P_t^{oil}$, and $C_t^{gas} = C_t^{oil}$, and suppose that there is no inflation, so the real and the nominal price of oil coincide. Finally suppose that the change in U.S. oil inventories is zero such that $C_t^{oil} = Y_t^{oil} + M_t^{oil} - X_t^{oil}$ (see Kilian 2017). Then simple substitution shows that the alternative purchasing power shock measure reduces to

$$-\frac{C_t^{oil} P_t^{oil}}{Y_t P_t^Y} \cdot \left(\frac{P_{t+1}^{oil} - P_t^{oil}}{P_t^{oil}} \right) \cdot \left(\frac{(M_t^{oil} - X_t^{oil})P_t^{oil}}{C_t^{oil} P_t^{oil}} \right),$$

or, equivalently,

$$-\frac{(M_t^{oil} - X_t^{oil})P_t^{oil}}{Y_t P_t^Y} \cdot \left(\frac{P_{t+1}^{oil} - P_t^{oil}}{P_t^{oil}} \right),$$

which up to the sign normalization is identical to the definition used by the Council of Economic Advisers (2014, 2016). Of course, there is no good reason for using any of these unnecessary simplifying assumptions, but this exercise illustrates that policymakers fully understand the need for normalizing by the expenditure share, directly refuting Ramey's (2017) claim in this regard. This discussion also helps explain why the approximate results reported in Council of Economic Advisers (2016), as discussed in section 5, are close to those in Baumeister and Kilian (2017). The reason is that both use fundamentally the same approach, except that the computations in Baumeister and Kilian (2017) are more precise.

9. To be precise, the Council of Economic Advisers (2014) works with net petroleum imports rather than net crude oil imports, where petroleum is defined as crude oil plus selected refined products, but it weights the nominal expenditure share for petroleum by the change in the price of crude oil. Thus, for expository purposes, it is preferable to treat the quantities of oil and gasoline as exchangeable and to denote net petroleum imports as net oil imports.

3.5. What Is the Economic Rationale for Weighting Real Gasoline Price Shocks by the Gasoline Expenditure Share?

In subsection 3.1, we explained intuitively why shocks to the real price of gasoline must be weighted by the gasoline expenditure share of consumers, when quantifying the discretionary income effect. Ramey (2017) makes the case that this approach is not supported by economic theory. She insinuates that fully specified economic models of the transmission of oil price shocks imply that the response of private consumption does not depend on consumers' energy share, rendering standard regression estimates of the discretionary income effect invalid.

This claim is not correct. Even granting that none of the currently available DSGE models provides a satisfactory representation of the real world, as noted by Kilian (2014), and that their quantitative implications are sensitive to ad hoc modelling assumptions, the fact that the impact of energy price shocks on the economy depends on the share of firm and household energy expenditures is well established. In fact, declines in the share of energy in production and consumption have been held responsible by many researchers for the reduced overall effect of oil price shocks on the U.S. economy in the literature (see, e.g., Edelstein and Kilian (2009), Blanchard and Galí (2010), Kilian and Vigfusson (2017)). The same point was made by Yellen (2011), as discussed earlier.

It is useful to review the theoretical rationale for the approach described in the preceding subsections. The DSGE model of Backus and Crucini (2000) referred to by Ramey is not helpful in answering that question because, in that model, households do not directly consume energy. Oil enters only into the production function. That assumption is typical for much of the DSGE literature on the transmission of oil price shocks, but fails to capture the reality that consumer spending on motor fuel is a major channel of the transmission of oil price shocks (see, e.g., Leduc and Sill 2004). In more recent DSGE models such as Dhawan and Jeske (2008a,b), which explicitly allow for household energy consumption, in contrast, the response of output to an exogenous real energy price shock depends on the household energy share. The economic rationale for weighting real gasoline price shocks is perhaps best illustrated by the New Keynesian DSGE model described in Blanchard and Galí (2010), which allows oil to enter both the utility function and the production function. The model makes no distinction between crude oil and gasoline. Blanchard and Galí (2010, p. 418) show that, in equilibrium, the relationship between real private consumption and real value added in an oil-importing economy is approximately

$$\log(C_t) = \log(Y_t) - \left(\frac{\alpha}{1-\alpha} + \frac{C_t^{\text{oil}} P_t^{\text{oil}}}{C_t P_t^{\text{CPI}}} \right) \log \left(\frac{P_t^{\text{oil}}}{P_t^{\text{PPI}}} \right),$$

where C_t is real private consumption, Y_t is real value added, α is the oil share in production, $C_t^{\text{oil}} P_t^{\text{oil}} / (C_t P_t^{\text{CPI}})$ is the oil expenditure share of consumers, and $P_t^{\text{oil}} / P_t^{\text{PPI}}$ is the real price of oil. This expression may be viewed as a generalization of equation (1). Given that α is quite small and that there is little difference between the PPI and the CPI, this expression can be approximated by

$$\log(C_t) \approx \log(Y_t) - \left(\frac{C_t^{\text{oil}} P_t^{\text{oil}}}{C_t P_t^{\text{CPI}}} \right) \log \left(\frac{P_t^{\text{oil}}}{P_t^{\text{CPI}}} \right),$$

which provides direct theoretical support for regression specification (3) and refutes Ramey's claim that this specification has no theoretical support.

4. ARE THE REGRESSION ESTIMATES IN BAUMEISTER AND KILIAN (2017) INVALIDATED BY STRUCTURAL BREAKS?

In addition to questioning the motivation of the regression model used to estimate the discretionary income effect and its specification, Ramey also raises concerns about the structural stability of these regressions. She presents evidence that the cumulative impulse response of private consumption changes, when splitting the sample in January 1993. It is worth noting that her evidence is not based on the regression specification of Baumeister and Kilian (2017). Rather, she reports results of a local projection model for the log-level of private consumption. This model specification involves estimating many more parameters than the original specification in Baumeister and Kilian (2017) and is known to be unreliable in small samples, so the estimates reported by Ramey have to be viewed with some caution (see Kilian and Kim (2011); Kilian and Lütkepohl (2017)). Clearly, however, qualitatively similar facts could be established for the original specification in Baumeister and Kilian (2017). In fact, as Ramey (2017) concedes, there is nothing new about her evidence. Essentially the same point was already made in Edelstein and Kilian (2009), who also discussed the causes of this time variation.

In discussing the structural stability of the estimates in Baumeister and Kilian (2017), it is useful to work with the exact specification used in that paper. Table 2 reports the cumulative response of real private consumption to a one standard deviation purchasing power shock after 20 months (corresponding to the length of the 2014.7–2016.3 episode). All results are based on the baseline model (3). The first row shows the full-sample estimate implied by this model. The next two rows in the table report the corresponding estimates for the two subperiods considered by Ramey (2017). Table 2 shows that the estimate based on the subsample 1970.2–1992.12 is 3.4 times larger than the estimate based on the subsample 1993.1–2016.3.

The difference across subsamples is not nearly as large as implied by the inefficient local projection estimator employed in Ramey (2017), but still large. This difference, which was emphasized by Ramey, moreover, is irrelevant for Ramey's argument that the estimates in Baumeister and Kilian (2017) are misleading. If there were a structural change, as asserted by Ramey, the analysis in Baumeister and Kilian (2017) would be in error to the extent that the full-sample estimate (which Ramey did not report) differs from the estimate based on the second subsample. The value of the response estimate for the first subsample is immaterial for answering that question. Table 2 shows that the full-sample estimate of 0.12 is not much larger than the estimate of 0.07 for the second subsample. It is this much more modest difference in estimates that requires an economic explanation.

This difference may still seem too large for comfort, but what Ramey fails to mention is that there are well-known reasons for the apparent instability in the regression coefficients, when the model is evaluated on subsamples. Such instability is in fact expected based on previous research, even in the absence of any structural breaks in the data-generating process. Although the average responses of real consumption to purchasing power shocks may be estimated reliably using long

enough samples, when considering short subsamples, these responses will change in magnitude and even in sign, as the composition of oil demand and oil supply shocks evolves over time, giving the mistaken appearance of structural instability, even when there is no structural change at all (see, e.g., Kilian (2008; 2009a,b); Kilian and Park (2009)). For example, as discussed in Edelstein and Kilian (2009), the real gasoline price in the second half of Ramey's sample is dominated by unexpected shifts in the flow demand for crude oil, which cushion the direct effect of oil price fluctuations on the U.S. economy. Thus, there is no mystery as to why the response estimates are much lower in the second half of the sample. This result simply reflects changes in the composition of oil demand and oil supply shocks.

This point may be illustrated empirically. The second subsample chosen by Ramey is known to include few important supply and storage demand shocks. Instead, it is dominated by flow demand shocks for oil, making it unrepresentative for the sample as a whole as well as unrepresentative for the period since June 2014 (see, e.g., Kilian and Murphy 2014). By slightly extending the second subsample to include the invasion of Kuwait in 1990, which constitutes an important shock to oil supply and to the storage demand for oil, the estimate for the second subsample increases from 0.0692 to 0.0997. The latter estimate is very close to the full-sample estimate of 0.1194 (see Table 2), suggesting that there is no instability at all. In fact, using model estimates based on the full sample, as in Baumeister and Kilian (2017), makes sense in analyzing the effects of the 2014–16 oil price decline, because the real price of oil during that episode was driven by a combination of different demand and supply shocks rather than primarily by flow demand shocks (see Baumeister and Kilian (2016); Kilian (2017)).

It is conceivable, of course, that there are other reasons for the decline in the response of private consumption that are unrelated to changes in the composition of oil demand and oil supply shocks. Ramey provides three specific reasons why she believes that the effect of oil and gasoline price shocks should have declined. First, she suggests that real oil price shocks caused larger overall terms-of-trade fluctuations in the 1970s and early 1980s than in recent years. This argument is missing the point. To start with, Ramey misrepresents Backus and Crucini's (2000) work. There are no exogenous real oil price shocks in their model, so Backus and Crucini could not possibly have quantified the causal effects of real oil price shocks. What they actually showed was that the time variation in the dynamic correlation between the real price of oil and the U.S. terms of trade reflects changes in the composition of oil demand and oil supply shocks. In their words:

“... since our dynamic general equilibrium model predicts that the economy responds differently to oil supply shocks than to other shocks, changes in their relative importance help to account for the unstable correlations in the data” (p. 185).

This point and its implications have already been addressed in our earlier discussion. Moreover, there is no *a priori* presumption that the real price of oil and the overall terms of trade of the U.S. economy should move proportionately. Clearly, the terms of trade are subject to many more shocks than real oil price shocks, so the weakening unconditional co-movement between the real price of oil and the overall U.S. terms of trade, as displayed in Figure 1 of Ramey (2017), is not evidence of a structural change in the data-generating process.

Second, Ramey insists that the terms of trade are affected by U.S. gasoline price controls and rationing. She proposes scaling the nominal gasoline price underlying the regressions in Baumeister and Kilian (2017) by a multiplicative factor as used in Ramey and Vine (2011). This adjustment is intended to capture the cost to consumers of waiting at gas stations, which arose during 1973.12–1974.5 and in 1979.5–1979.7, when the government imposed gasoline price ceilings in

response to oil price increases. Because this waiting cost is not associated with a transfer of real income abroad, however, this adjustment must not be used in quantifying the discretionary income effect. This misunderstanding is closely related to Ramey's failure to appreciate that purchasing power shocks reflect real income transfers abroad.

Finally, Ramey argues that declines in the share of oil imports explain the smaller cumulative response of private consumption in the sample starting in January 1993. That argument was already dispensed with in section 3, where we showed that the response of private consumption in 2014–16 is quite similar, whether we allow for changes in the dependence on oil and gasoline imports or not. Likewise, Baumeister and Kilian (2017) stressed that their substantive conclusions are unaffected by this adjustment. Thus, the evidence and arguments in Ramey (2017) regarding potential structural instabilities in the regression model of Baumeister and Kilian (2017) are not valid.

5. WHITHER REGRESSION ANALYSIS?

As stressed by Ramey (2017), the estimates in Baumeister and Kilian (2017) are very close to the “direct effects” of lower oil prices on U.S. real GDP growth reported in the *2016 Economic Report to the President* (Council of Economics Advisers (2016), Box 2-1, p. 55–58) based on a simple back-of-the-envelope calculation. This report argued that if one values all U.S. net imports of crude oil and petroleum products at the nominal price of crude oil, then, given the cumulative decline in this price since June 2014, all else equal, we would expect a 0.1% increase in U.S. real GDP in 2014 and an additional increase of 0.2% in 2015. The implied cumulative increase in real GDP after mid-2014 is about 0.3%, which is remarkably close to the net stimulus of 0.39% estimated in Baumeister and Kilian (2017). Likewise, for private consumption the estimate of 0.6 in the *Report* is close to the estimate of 0.7 in Baumeister and Kilian.

The overall tenor of Ramey's analysis is that the effects of unexpectedly lower oil prices on consumption should be systematically smaller than the estimates reported in Baumeister and Kilian (2017), yet at the same time she is forced to acknowledge that these estimates are similar to those obtained in the *Report*, which she considers correctly executed. Our analysis suggests that it is not an accident that the *Report* reaches conclusions similar to Baumeister and Kilian (2017). As shown in section 3.4, both studies measure purchasing power shocks in fundamentally the same way, the key difference being that Baumeister and Kilian (2017) dispense with the restrictive assumptions underlying the analysis in the *Report*.

This is not the only difference, however. The *Report* is careful to stress that care is required in interpreting its estimate of the “direct effect,” because “consumers for whom lower gasoline prices freed up income for other purchases ... may take time ... to make additional purchases, so the timing of the additional spending may lag the declines in oil prices” (p. 56). Nor do the estimates in the *Report* account for additional multiplier effects from changes in spending (p. 56). Thus, these direct estimates conceptually differ from the cumulative effect estimated by Baumeister and Kilian (2017). Unlike the estimates cited in the *Report*, Baumeister and Kilian's (2017) estimates account for typical delays in spending as well as multiplier effects.

Perhaps most importantly, the analysis in Baumeister and Kilian (2017) explicitly recognizes the fact that consumer responses depend on the real price of gasoline rather than on the real price of oil, and it accounts for the timing and persistence of changes in the real price of gasoline on a month-by-month basis, allowing more accurate estimates of the cumulative effects and providing more information about the evolution of these cumulative effects month by month. Their analysis also dispenses with a number of other simplifying assumptions, as discussed in section 3.4. Thus,

the fact that the back-of-the-envelope estimates in the *Report* are in the same ballpark as those in Baumeister and Kilian (2017) was by no means obvious *ex ante*. Back-of-the-envelope computations of this type are best viewed as a preliminary approximation to be validated by more formal regression-based methods of the type discussed in this paper rather than as a substitute for more formal analysis.

6. CONCLUSION

The discretionary income effect is a central element of the transmission of oil price shocks, as discussed in the existing literature. Recently, Ramey (2017) has suggested that empirical studies quantifying this effect such as Edelstein and Kilian (2009), Hamilton (2009, 2013), and Baumeister and Kilian (2017), among others, have no economic foundation. She not only disputed the very existence of a discretionary income effect, but she called into question the stability of commonly used regression models in this literature, and she even questioned the data used by these models. Ramey's critique is remarkable in that she does not provide any constructive alternative modeling approaches, but implies that regression models are simply not necessary to assess the questions of interest.

Our analysis showed that Ramey's central claim that the discretionary income channel makes no economic sense is mistaken. In fact, the shocks to discretionary income discussed in the literature (also referred to as purchasing power shocks) are substantively identical to the shifts in real domestic income associated with a terms-of-trade shock stressed by Ramey. The specification of conventional regression models of the discretionary income effect is fully consistent with recent New Keynesian DSGE models of the transmission of oil price shocks. Moreover, these regression models are already designed to deal with many of the concerns raised by Ramey. We discussed generalizations of these models and assessed the robustness of standard specifications to the concerns raised by Ramey.

We also demonstrated that the model specifications and diagnostics used by Ramey to establish the structural instability of regression models of the transmission of oil shocks are flawed. We showed that her modelling approach ignores recent developments in the literature, and we explained why the data modifications proposed by Ramey are inappropriate in the context of this literature. Finally, we discussed the importance of regression analysis in quantifying the effects of oil price shocks. We concluded that there is no reason to rewrite the literature on the transmission of oil price shocks.
